ABSTRACT

Background: Neoplasia of the urinary bladder is common in dogs, accounting approximately 0.5 to 1.0 percent of all neoplasms. Most of the neoplasia of the urinary bladder is epithelial in origin and only 10% of urinary bladder neoplasms in dogs are from mesenchymal origin, of which the most frequent types are leiomyoma / leiomyosarcoma, and hemangioma / hemangiosarcoma. Virtual autopsy refers to the postmortem use of radiology, ultrasound and cross-sectional imaging prior to conventional necropsy. This paper reports the detection of a rare extra-luminal urinary bladder mass diagnosed as leiomyoma with a virtual autopsy techniques.

Case: A 16-year-old male Schnauzer had previous history of seizure and no complains related to the urinary system. The animal was treated symptomatically to the neurological signs and responded to medical treatment. Nine weeks later from the first visit to the hospital the dog was found dead at home. Then postmortem ultrasound and computed tomography of the abdomen were performed. Postmortem ultrasound revealed a homogenously hypoechoic, rounded and slightly irregularly margined mass located externally but adjacent to the left cranial wall of the urinary bladder and appears to extend from its serosal margins. Postmortem computed tomography was performed after postmortem ultrasound. A pedunculated homogenous soft tissue attenuating mass was located at the left lateral aspect of the urinary bladder and extended cranially. It had a stalk that connected to the left lateral wall of the urinary bladder. A partial necropsy of the abdomen was done just to examine the mass. A round extraluminal, pedunculated mass was observed at the left lateral aspect of the urinary bladder wall. It was pale pink on the outside and white inside, with a soft to firm consistency. The lumen and mucosal surface of the urinary bladder was smooth and regular. The histology of the mass revealed a densely cellular neoplastic proliferation, expansive, composed of spindle-shaped cells with moderate to large eosinophilic cytoplasm, sometimes wavy and with indistinct edges. The nuclei were large, oval to flattened, with dense chromatin and inconspicuous nucleoli. Anisocytosis and anisokariosis were discrete and no mitotic figures were observed. The arrangement consisted of dense, irregular and multidirectional bundles and the stroma was scarce. The mass was histologically confirmed as leiomyoma.

Discussion: In this case, we performed postmortem ultrasound and computed tomography as part of a virtual necropsy study and in both modalities the urinary bladder mass was able to be identified, followed by a partial necropsy to further investigate the nature of the mass and to collect a sample to obtain the histological diagnosis. A few of the disadvantages of the postmortem ultrasound and computed tomography specially in this case were the lack of color Doppler investigation on ultrasound and the lack of evaluation of the patten of contrast enhancement on computed tomography. These techniques could have added important information related to the vascularity characteristics of the mass in a live patient. This is the first case report in veterinary medicine that describes an extra-luminal pedunculated urinary bladder leiomyoma in a canine patient, and it is emphasized the approach by postmortem ultrasound, postmortem computed tomography and conventional necropsy findings to reach the definitive diagnosis.

Keywords: virtual necropsy, urinary neoplasm, post mortem imaging diagnosis.

INTRODUCTION

Neoplasia of the urinary bladder is common in dogs, accounting approximately 0.5 to 1.0 percent of all canine neoplasms [4]. Most of the neoplasia of the urinary bladder is epithelial in origin and only 10% of urinary bladder neoplasms in dogs are from mesenchymal origin, of which the most frequent types are leiomyoma / leiomyosarcoma, and hemangioma / hemangiosarcoma [2,4]. Urinary bladder leiomyoma / leiomyosarcoma are rare and only represent 0.5 to 4 percent of all canine urinary bladder neoplasm [7,9].

Canine leiomyoma / leiomyosarcomas has been described as a single, rounded and well-defined intraluminal mass, with mixed echogenicity and lack of detectable blood flow on color Doppler mode [2,3]. In human medicine, leiomyomas are classified according to the anatomic location of the mass as endovesical, intramural and extravesical [6]. Intramurals leiomyosarcoma and leiomyoma have been reported in humans [1,10]. The reported HU of leiomyoma of the urinary bladder in human is equivalent or slightly higher than muscle, and approximately >40 after contrast enhanced [12]. The most commonly seen clinical signs of urinary bladder leiomyoma are urinary incontinence and a palpable caudal abdominal mass [5,8].

Virtual autopsy refers to the postmortem use of radiology, ultrasound and cross-sectional imaging prior to conventional necropsy [11]. In this case report we demonstrate the detection of a rare extra-luminal urinary bladder mass diagnosed as leiomyoma with a postmortem ultrasound (PMUS) and postmortem computed tomography (PMCT) techniques.

CASE

The body of a 16-year-old male intact Schnauzer was presented for necropsy. The dog had previous history of seizure and no complains related to the urinary system. The animal was treated symptomatically to the neurological signs and responded to medical treatment. Nine weeks later from the first visit to the hospital the dog was found dead at home. The owner consented to donate the cadaver to participate in a virtual necropsy study in which both postmortem ultrasound (PMUS) and postmortem computed tomography (PMCT) were performed. A partial necropsy just to further assess the PMUS

and PMCT findings was performed and a sample of the mass found in the urinary bladder was sent to histological examination.

Postmortem ultrasound of the abdomen was performed using a ultrasound system (MyLabTM40 VET)¹ with a linear transducer (3.5-11MHz). Whole body PMCT was performed with a CT helical multislice scanner (MX8000 IDT 16-row)². The technical settings were 120 kVp, 240 mAs, 200 mm field of view, 512 x 512, and the study were acquired with a slice thickness of 3 mm and 1.5 mm of reconstruction interval. The study was acquired with the soft tissue algorithm and in helical mode.

Postmortem ultrasound revealed a homogeneously hypoechoic (compared to the echogenicity of the urinary bladder wall), rounded and slightly irregularly marginated mass located externally but adjacent to the left cranial wall of the urinary bladder and appears to extend from its serosal margins (Figure 1). After administration of 10 mL of tap water via urinary bladder catheter, the mass was confirmed to originate from the muscularis layer of the urinary bladder wall. The mass measured approximately 2.9 cm in length by 1.4 cm in height by 2.3 cm in width.

Postmortem computed tomography was performed after PMUS. A pedunculated homogenous soft tissue attenuating mass (HU=72) was located at the left lateral aspect of the urinary bladder and extended cranially. It had a stalk that connected to the left lateral wall of the urinary bladder. The stalk was approximately 6 mm in diameter (Figure 2). The

Figure 1. Ultrasound image of the mass: Transverse image of the homogeneously hypoechoic extraluminal mass (between the black arrows) of the urinary bladder (UB). The urinary bladder is not fully distended; thus the wall appears thick. The stalk between the mass and the urinary bladder is not visualized, probable due to close proximity of both.

Figure 2. Computed tomography image of the mass: Dorsal reconstruction of PMCT study at two different level. Black arrows indicate the margins of the extraluminal, pedunculated soft tissue attenuating mass. White arrow heads demarcate the stalk of the mass. A- is located at a more dorsal level and B- is located at a more ventral level. The descending colon (DC) is located adjacent to the cranial and lateral margins of the mass. UB = urinary bladder.

Figure 3. A- Gross necropsy shows the pedunculated mass originates from the left lateral wall of the urinary bladder. B- The mucosa of the urinary bladder is normal.

mass measured approximately 2.9 cm in length by 2.0 cm in height by 2.2 cm in width. The remaining findings of the PMCT were unremarkable.

A partial necropsy of the abdomen was done just to examine the mass. A round extraluminal, pedunculated mass was observed at the left lateral aspect of the urinary bladder wall. It was pale pink on the outside and white inside, with a soft to firm consistency (Figure 3a). The lumen and mucosal surface of the urinary bladder was smooth and regular (Figure 3b). The histology of the mass revealed a densely cellular neoplastic proliferation, expansive, composed of spindle-shaped cells with moderate to large eosinophilic cytoplasm, sometimes wavy and with indistinct edges. The nuclei were large, oval to flattened, with dense chromatin and inconspicuous nucleoli. Anisocytosis and anisokariosis were discrete and no mitotic figures were observed. The arrangement consisted of dense, irregular and multidirectional bundles and the stroma was scarce. The mass was histologically confirmed as leiomyoma. The stalk of the mass was not well represented in the histological block.

DISCUSSION

In this case, we performed PMUS and PMCT as part of a virtual necropsy study and in both modali-

ties the urinary bladder mass was able to be identified, followed by a partial necropsy to further investigate the nature of the mass and to collect a sample to obtain the histological diagnosis. A few of the disadvantages of the PMUS and PMCT specially in this case were the lack of color Doppler investigation on US and the lack of evaluation of the pattern of contrast enhancement on CT. These techniques could have added important information related to the vascularity characteristics of the mass in a living patient.

This report describes an unusual extraluminal, pedunculated canine urinary bladder leiomyoma. The smooth and well-defined aspect of the mass margins was similar to previous report [7]. However, the mass of this report was homogeneously hypoechoic rather than heteroechoic [7]. The fluid administration to distend the urinary bladder helped to reduce the surface area of contact between the mass and the urinary bladder, making the identification of the origin of the mass possible. The PMCT helped to identify the stalk connecting the mass to the urinary bladder wall. The Hounsfield unit and homogenous attenuating nature of this mass is similar to reported cases in human. [5,8].

No history of incontinence was reported in this case, perhaps due to extraluminal and pedunculated nature of the mass. We failed to palpate this mass maybe due to its small size and also its close proximity to the colon.

Due to lack of complete history, the probable cause of death in this animal was not determined. As there were no abnormalities in the thorax or abdomen to explain the cause of death in this dog, recurrent neurological sign (seizures) that lead to death could not be ruled out. In our case, the unusual location of the urinary bladder tumor was the motivation for this report.
