ABSTRACT

Background: Accidents caused by venom of *Crotalus durissus* snakes, popularly known in Brazil as rattlesnake, are second in relation to the occurrence and first place in deaths in humans and animals, mainly due to the great neurotoxic, myotoxic, coagulant, nephrotoxic and hepatotoxic potential of their venom. The effects observed are due to the action of the main poison fractions and among them we can mention crotoxin (representing 50% of the total poison), crotamine, gyroxine and conxulxin. The present study aimed to analyze the liver of experimentally poisoned Wistar rats with venom of *Crotalus durissus terrificus* by means of histological and fractal analysis. The hypothesis is that the venom of *Crotalus durissus terrificus* can induce hepatic damage at the dose recommended in this study, that its alterations can be quantified by the fractal dimension and that the antiofídico serum botrópico crotálico be able to minimize the hepatic lesions induced by the venom.

Materials, Methods & Results: Ninety rats were distributed into different groups and treated with: control group (GC, n = 30) 0.9% sodium chloride solution; venom group (GV, n = 30) crotalic venom at the dose of 1 mg/kg; (GVS, n = 30) crotalic venom at the dose of 1 mg/Kg and antiofídico serum 6 h after the application of the venom at the dose recommended by the manufacturer. Liver samples were collected at 2 h (M1), 8 h (M2) and 24 h (M3) after venom administration and submitted to histological analysis and fractal dimension (DF) using the ImageJ® software and box-counting method. Procedures for collecting, processing and analyzing samples were standardized. For statistical analyzes, after the normality was verified by the Shapiro-Wilk test and homogeneity by the Bartlett test, the data were submitted to analysis of variance (ANOVA) with Duncan test contrast with a significance level of 5%. No significant lesions were observed in GC, however necrosis, cytoplasmic and nuclear vacuolization and absence of inflammatory infiltrate were observed in 8 h (M2) and 24 h (M3) in GV. In addition to the lesions found in the GV, mononuclear inflammatory infiltrate was evident always (2 h, 8 h and 24 h) in the GVS. The lesions of necrosis, cytoplasmic and nuclear vacuolization, considered of greater severity were visualized in M3 (24 h) in both GV and GVS. There was an increase in DF for the same changes in GV and GVS over time, but with no difference between them, but with a significant difference compared to CG. In this study, lesions evidenced in the liver were not minimized by the application of antiofídico serum at the recommended dose and during the time of observation of the animals.

Discussion: This study agrees with other authors about the hepatotoxicity of crotalic venom in relation to histological findings and the results indicate an increase in DF for the findings of vacuolization and necrosis, proving to be an efficient method for the quantitative evaluation of morphological changes induced by venom without observer interference. In addition, non-protection of the liver by antiofídico serum was evident. It is concluded that *Crotalus durissus terrificus* venom causes important hepatotoxic effects in the first 24 h after experimental intoxication in rats; DF is effective in the quantitative morphological evaluation of liver changes and was characterized mainly by vacuolization and necrosis; the antiofídico serum did not protect the liver from lesions induced by crotalic venom according to the dose of venom and antiofídico serum and time of observation recommended in this study.

INTRODUCTION

Serpents of the genus *Crotalus durissus* they inhabit regions of the Federal District, São Paulo, Mato Grosso, Goiás and Southern Region [4,6,23,32].

The venom of *Crotalus durissus terrificus*, consisting of an organic fraction corresponding to 90% of dry weight, which contains proteins, hydrolytic enzymes, non-hydrolytic enzymes, proteolytic enzymes, crotalina [1,31]. The inorganic fraction representing approximately 10% of the dry weight. [5,23].

Hepatotoxicity has been reported in some studies, however, most of the time the findings are from cases attended after the accident, and few are from histopathological findings in the induction of the accident in experimental form. [2,3,13,14,16, 22].

A new diagnostic tool called fractal analysis has been cited in some studies as a method of quantifying changes in cells such as retina [11], hepatocytes [27], renal and pulmonary vasculature [10,17,34], cardiac studies [12,18,26,33,35] and neoplasms [7].

The fractal analysis allows a more precise comparison on the size of the tissue lesions found in histological slides and the box-counting technique is one of the most used [19,21].

In this context, the objective of the present study aimed to analyze the liver of experimentally poisoned Wistar rats with venom of *Crotalus durissus terrificus* by means of histological and fractal analysis. The hypothesis is that the venom of *Crotalus durissus terrificus* can induce hepatic damage at the dose recommended in this study; that hepatic changes can be quantified by the fractal dimension and that the antiofídico serum is able to minimize the hepatic lesions induced during the evaluation period of the study.

MATERIALS AND METHODS

Animals and experimental groups

The experimental procedures used throughout the study were approved by the Ethics Committee on the use of animals from the University of origin.

Ninety animals were divided into three groups, being control group (CG, n = 30), treated with 0.9% sodium chloride solution; venom group (GV, n = 30), treated with crotalic venom; venom and serum group (GVS, n = 30), treated with crotalic venom and antiofídico serum.

The animals were evaluated with 2 h, (M1) 8 h (M2) and 24 h (M3) after venom administration.

Center for the study of poisons and venomous animals

The venom of *Crotalus durissus terrificus* snake was provided by the Poisons and Venomous Animals Studies Center- (CEVAP)¹ of the Paulista State University (UNESP) – Botucatu, SP, Brazil. Poison inoculation was performed in the middle third of the lateral side of the left thigh of the rat, intramuscular (IM), at a dose of 1 mg/kg. Crotalic bothropic serum² was administered intraperitoneally 6 h after the administration of venom at the dose recommended by the manufacturer to neutralize the amount of venom inoculated. The 0.9% sodium chloride solution was administered in the control group in the middle third of the lateral side of the left thigh, intramuscularly.

Sampling and histological analysis

At different times of evaluation, 10 animals from each group were sacrificed with thiopental sodium at 150 mg/kg dose [20]. Liver samples were collected and conditioned in 10% buffered formalin, embedded in paraffin, cut into a 4 µm thick microtome, stretched on glass slides with a frosted end and subsequently stained with hematoxylin and eosin (HE).

The method of classification analysis of lesions and scores was made from Gerez *et al.* modified [15]. As shown in Table 1, the microscopic observations of the liver led to the identification of different lesions and severity allowing to establish a lesion score per animal. The minimum score was 0 and the maximum lesion score was 36.

Fractal dimension

The different tissue sections of the liver of Wistar rats were photographed using the LEICA microscope (model DM750)³ coupled to a video camera, which sends digital images to a computer equipped with Image Pro-plus⁴. All scanned microscopic images were captured at 800x600 resolution (400x magnification). To analyze the fractal dimension (DF), the stained images in HE (Figure 1A) went through the binarization process, making them black and white (Figure 1B) with the graph result showing the slope of the regression line with the values of the two logs (Figure 1C). The procedures were performed on ImageJ® software from the United States National Institutes of Health (NIH), available free of charge on the Internet (<http://rsbweb.nih.gov/ij/>). The box-counting method considers two dimensions, allowing the quantification of the distribution of pixels in this space, not consider-

ing the texture of the image [21]. This influences that two images with the same distribution of the pixels, one binarized and the other in gray levels, will have the same DF, so the DF calculated with the ImageJ® will always be between 0 and 2, not distinguishing different textures [24].

Statistical analysis

For statistical analyzes, after the normality was verified by the Shapiro-Wilk test and homogeneity by the Bartlett test, the data were submitted to analysis of variance (ANOVA) with Duncan's test contrast with a significance level of 5%.

Table 1. Scores of histological lesions found in the liver of Wistar rats.

Tissue	Type of lesions	Severity factor	Maximal scores
Liver	Apoptosis	6	36
	Inflammatory infiltrate	6	
	Necrosis	9	
	Cytoplasmic vacuolization	6	
	Nuclear vacuolization	3	
	Megalocytosis	6	
	Desorganization of hepatic cords	3	

*The score for each lesion was obtained by multiplying the severity factor with the extension of the lesion. The score of the organ was then obtained by the sum of each score of the lesion. Severity factor (or degree of severity), 1 = mild lesions, 2 = moderate lesions, 3 = severe lesions. The extent of each lesion (intensity or frequency observed) was evaluated and scored as 0 = no lesion, 1 = low extension, 2 = intermediate extension, 3 = large extension.

Figure 1. A- Histological section of liver [H&E; 400x]. B- Image of HE after binarization. C- Linear regression graph showing the slope of the regression line of the values of the two log.

RESULTS

In the histological analysis, no significant lesions were observed in the GC, however, in all GV and GVS animals, evident and severe lesions were observed and differed ($P < 0.05$) from the GC. Necrosis, cytoplasmic and nuclear vacuolization, mild disruption of

hepatocyte cord and absence of inflammatory infiltrate were observed in M2 (Figure 2) and M3 in GV animals.

For the GVS animals, the mononuclear inflammatory infiltrate was well evident at all moments, besides necrosis, cytoplasmic and nuclear vacuolization, and cord disruption of hepatocytes being accentuated in M3 (Figure 3).

The severity of the lesions was proportionally increasing as the evaluation time increased, being significant ($P < 0.05$) in the comparison between GV and GVS in M1 and M2 (Table 2).

The lesions of greater severity or intensity were visualized in GV and GVS in M3, however, there was no significant statistical difference ($P > 0.05$) between them at this time (Table 2).

Greater values of the fractal dimension for necrosis and cytoplasmic vacuolization were observed in GVS animals, in M2, followed by M3 and M1, while in GV the highest values were observed in M3, M2 and M1 respectively. Statistical differences ($P < 0.05$) were observed in GV and GVS animals in M2 and M3 compared to CG in M1 and M3 (Figure 4).

Table 2. Total lesion score of histology of liver samples.

	M1 (2 h)	M2 (8 h)	M3 (24 h)
Control group	5.60 ± 2.27^a	5.60 ± 1.26^a	6.22 ± 2.48^a
Venom group	10.22 ± 2.63^b	12.87 ± 2.03^c	17.12 ± 2.64^{ef}
Venom/serum group	16.00 ± 2.44^{de}	14.44 ± 2.06^{cd}	18.30 ± 1.76^f

Different letters in the same column indicate significant statistical differences between groups.

Figure 2. Hepatic photomicrography in venom (GV), 8 h (M2) after application of crotalic venom: Discrete disarray of hepatocyte cords, black arrow demonstrates apoptotic body, white arrow cariolysis [H&E; 400x].

Figure 3. Liver photomicrography in venom/serum group (GVS), 24 h (M3) after application of crotalic venom: Severe hepatocyte cord disarrangement, black arrow demonstrates pyknotic nucleus, red arrow cytoplasmic vacuolization [H&E; 400x].

Figure 4. Analysis of the fractal dimension (DF) in the control groups (GC), venom group (GV), venom/serum groups (GVC) at 2 h (M1), 8 h (M2) and 24 h venom.

DISCUSSION

In this study, the histological changes observed together with the increase in DF values, it is possible to report that the crotalic venom causes an injury of importance and severity in the liver of experimentally intoxicated animals with a dose of 1 mg/kg. Other authors have also reported moderate to severe liver damage in humans [2,3], mouse [13] and dog [30] as a result of the accident caused by the venom of *Crotalus durissus*.

Liver injury may vary in type, dose and duration of toxin exposure [20]. In hepatocyte reactions to toxic aggression, cellular swelling, steatosis, with or without cholestasis can be observed, and in more severe cases, it may progress to necrosis and hepatic insufficiency. In this way, we can affirm that the dose of 1 mg/kg of crotalic venom used in this study induced lesions after 2 h of venom application and progressed over time to more severe and severe lesions such as necrotic cytoplasmic vacuolization and apoptosis.

The crude venom of the *Crotalus durissus terrificus* snake exerts significant effects on the liver and is related not only to metabolism, but to oxidative stress and mitochondrial functions [9].

The findings of the present study corroborate with another author reporting serious injuries, such as necrosis, which is established two hours after the application of the venom and intensified throughout the evaluation. In addition, the author describes that the antiofídico serum tested alone may contribute to damage to the liver [28].

In this study the fractal dimension was applied for the first time in the analysis of lesions induced by ophidian venom, and no similar study was found in the literature. Its application was performed in the lesion of greater occurrence and severity, that is, vacuolization and necrosis.

In current studies, on the action of venom of ophidians in various tissues and organs histological analysis is performed qualitatively through tissue characteristics, cell morphology, size, nucleus position, presence of inflammatory infiltrate, and other findings [28-30]. However it is known that this type of analysis is dependent on the analyzer, which leads to intra and interobserver variations [21]. Unlike this method, fractal analysis, in addition to quantifying histological

changes, is independent of the evaluator, since it is an automatic analysis performed by software [25].

In the fractal dimension when we submitted HE-stained blades to the binarization process, the nuclei are detached from the rest of the cells, so it is possible to measure the size of the infiltrate or other findings by the analysis of its fractal dimension [25].

The findings of this study show that DF is a tool that can be used as a means of quantitative analysis of a lesion, which adds to the study an independent evaluation of the evaluator. Although there were not many significant statistical differences in the comparison between the groups, the fractal dimension analysis showed that animals poisoned by venom and even those submitted to treatment with antiofídico serum showed an increase in the fractal dimension in comparison to CG animals, suggesting that they have a larger fractal dimension. Irregular structures, when analyzed by DF, are quantified with respect to their complexity, thus, higher DF values are related to more complex images [8] and [21]. Although the evaluation of lesions by histology and DF has been efficient, other studies should be carried out in the same or different species for a better understanding of the liver damage caused by crotalic venom, as well as the evaluation of the effects of the antivenom.

CONCLUSIONS

It is concluded that *Crotalus durissus terrificus* venom has hepatotoxic effects and fractal dimension is effective in morphological evaluation of the liver and antivenom did not protect the liver from lesions caused by venom.
